(Dated: August 28, 2008)

We develop a stochastic, individual-based model for food web simulation which in the large-population limit reduces to the well-studied Webworld model, which has been used to successfully construct model food webs with several realistic features. We demonstrate that an almost exact match is found between the population dynamics in fixed food webs, and that the demographic fluctuations have systematic effects when the new model is used to construct food webs due to the presence of species with small populations.

Keywords: ecological diversity; demographic stochasticity; ecological community model

I. INTRODUCTION

There is a crucial distinction in biology between the proximal causes of phenomena and the evolutionary explanation [1]. While the former is useful in giving specific insight into a system being studied, it is only through the understanding of the evolutionary mechanisms in action that general principles can be understood. Applying this understanding to ecosystems, the proximal explanation of food web structure relates to the identity and habits of the species within it [for example 2, 3], but the underlying, evolutionary explanation requires understanding of the emergence and stability of those inter-specific relations which contribute to the food web. Whereas alternative models of food web structure such as the niche model [4] and the cascade model [5] are essentially static with respect to their species composition, the Webworld model [6] has been used to demonstrate the formation of complex food webs stable to evolutionary perturbation with several emergent features consistent with observed ecosystems [7, 8, 9]. One aspect of real ecosystems which it has not been possible to reproduce in the Webworld model is the existence of oscillations about a fixed point in the population dynamics. Historic studies of population dynamics have tended to focus on systems which experience oscillations, such as the Snowshoe Hare [10], or Great Tit [11], but the Webworld model shows monotonic approach towards a fixed point. In part this is a consequence of using population dynamics continuous in time, since chaotic dynamics often emerge when large overshoots of the carrying capacity are possible [12], an effect mitigated by using very small time steps or effectively continuous dynamics. Křivan & Eisner [13] demonstrate the occurrence of limit cycles and chaotic behaviour even using continuous population dynamics and a Holling type II functional response. It is likely that the explicit competition term in the functional response used by Webworld prevents these cycles occurring. It was, however, demonstrated by McKane & Newman [14] that cyclic behaviour could arise in a model using finite populations which disappears when the infinite population limit is taken. Since the continuous population model of Webworld is equivalent to this limit, one explanation for the absence of realistic population cycles is the absence of individuals from the model, whose demographic stochasticity could potentially lead to resonant oscillations in the population dynamics.

Stochasticity in ecosystem models tends to be divided into the three categories described by Lande *et al.* [12]. The first of these, demographic stochasticity, is simply the result of considering small numbers of entities in a system. For large populations, the law of large numbers tends to ensure that birth and death processes, happening at random to unrelated individuals, nevertheless average out so that differential equations are an adequate description of the processes. For small populations it may be essential to the future of a species how many, when, and in what order births and deaths occur. In the case of most ecosystems, including those modelled by Webworld, there exist at least some species with small populations [15, 16]. If these species exert an influence on the ecosystem as a whole, for instance by having a role as a top predator [17], the dynamics of the system may crucially depend on the demographics of species with small populations, and as a consequence demographic stochasticity cannot be neglected even for the understanding of the broader ecosystem. The related effect of demographic heterogeneity, characterised by Melbourne & Hastings [18], concerns the demographic stochasticity within species of groups of heterogeneous individuals, for example males and females. Even if the population of the species as a whole were constant, the sex ratio is generally not strongly constrained by effects such as prey abundance in the same manner as the population of the species as a whole, and hence is more vulnerable to large-amplitude fluctuations. The Webworld model does not explicitly incorporate sexual reproduction, or distinguish between individuals by sex, but in Section III C we show that demographic heterogeneity

in terms of foraging strategy can have important consequences for the food web. The two further types of stochasticity discussed by Lande *et al.* [12] are not examined in this paper. Of these, environmental stochasticity, and indeed environmental periodicity, could be incorporated into the Webworld model, but the work of McKane & Newman [14] indicates that the intrinsic fluctuations of demographic stochasticity are sufficient to have large scale consequences on the population dynamics. Because demographic stochasticity can be naturally generated by the probabilistic occurrence of events with characteristic frequencies, we feel that it is more natural to introduce this as the first form of stochastic influence on food web structure than to apply an external forcing, which would require additional assumptions about the level at which it acts (basal resource availability, death rate, etc.) and the degree to which the effects on different species were correlated. In this paper we therefore develop an individual-based model designed to replicate Webworld in the large-population limit. The final common type of stochasticity relates to measurement error. As a measurement of a real ecosystem will not yield an exact count of all individuals of each species, the dynamics of the real system will differ from those that would occur if the measurements were correct. As such, even measurements of a constant population will show apparent fluctuations. Since the Webworld mathematical model utilises exact populations, the population records are at any moment in time precise, and this form of stochasticity is not relevant in this case.

A second aim of this work is to introduce a model to which the results previously published for Webworld are an approximation, valid under conditions which need to be properly understood. It is more difficult to obtain precise results for the more detailed model developed in this paper than for the parent Webworld model, either analytically or numerically. The parent model remains the most appropriate level of detail at which to derive gross properties of large ecosystems with relative computational economy. In addition, food webs established in the parent model can be used to grow food webs adapted to stochastic population dynamics. Imported food webs can either be used as the basis for on-going evolution, or species can be drawn from a parent-model 'mainland' to construct immigrant communities, as is done in the present paper. By working towards a model in which individual actions can be described, the consequences of differing plausible behaviours can be examined. In particular, an individual-based model such as that introduced in this paper is the appropriate level of detail at which to examine foraging strategy, or can be considered as an essential step in deriving an agent-based model in which experience-derived strategy optimisation, and life-history effects, can be examined. The approach taken in this paper is to model species by discrete individuals, who are affected by events such as death or the slow digestion of consumed prey, and who interact in a pair-wise manner between predators and prey. This approach has the virtue that it can be formally described in the same manner as a set of chemical reactions, and the Gillespie algorithm [19] can be used to simulate essentially exact and typical histories. In Section II we expand on the nature of this description; in Section II A we recap those aspects of the Webworld model, more fully expounded in Drossel *et al.* [6], which are necessary to derive the individual-based model. This derivation is presented in Sections II B to II D. In Section II E we describe variants on the basic model relating to foraging strategy selection in order to investigate the sensitivity of the Webworld model to assumptions about decision making which cannot be adequately investigated using continuous population dynamics. A summary of the stochastic model is given in Section II F.

II. MODEL

The Webworld model from which results have been published in previous papers [7, 8, 9, 20, 21] is stochastic to the extent that species are added as random mutants of a randomly selected parent species, but the behaviour of the system between speciation events is entirely deterministic. In particular, the population dynamics is represented by a set of differential equations linking the rate of change of the population of each species to its own population as well as the populations of its prey, competitors and predators. This is notably similar to the representation of the dynamics of a chemical system in terms of reaction rates. Using the insight that such deterministic reaction rate equations emerge from large numbers of interactions of discrete molecules, and the desire to model ecosystem dynamics in terms of individual organisms, in this paper we deduce the corresponding set of reactions which gives rise to the Webworld model as its expected behaviour. Interactions changing the state of individuals will be written after the manner of chemical reactions, which follow the general model

$$\mathrm{X_A} + \mathrm{X_B} \xrightarrow{k} \mathrm{X_C}, \qquad [\mathrm{I}]$$

where X_A and X_B are individuals present before the interaction, of types A and B respectively, and X_C is the individual of type C which remains after the interaction. Writing the abundance of these types in turn as N_A and N_B, the total rate at which [I] occurs is given by

$$R = kN_AN_B, \tag{1}$$

where k, written over the reaction arrow of [I], is the reaction rate coefficient. Concrete examples of reactions are given in Section II B. In the Webworld model the rate of predation is determined by a ratio-dependent functional response, which we expect to be encoded in the appropriate reaction rate coefficients.

Having chosen to make the stochastic Webworld model reaction-based, an efficient means of implementing the dynamics in an essentially exact manner is to use the

Gillespie algorithm [19]. One of the assumptions we retain in order to use this method is that spatial effects are not relevant; in a chemical reaction scheme this is equivalent to supposing the system to be well-mixed. Under this assumption the reaction rates can at all times be calculated in terms of the abundance of the reactants without regard to their distribution. The original Webworld model makes similar assumptions about the absence of spatial structure and hence is well-matched. A model incorporating spatial structure is likely to use spatial considerations as the basis of the functional response underlying Webworld, and may therefore need to describe in detail the individuals of each species and their particular behaviour. In addition to the direct interest in the effects of demographic stochasticity on the assembly and functioning of ecological communities, the model described in this paper can be understood as a necessary step towards an agent-based model which could explore the effects of individual-level behaviour and spatial inhomogeneity.

For conciseness we will refer to the Webworld model with deterministic population dynamics, discussed in Drossel *et al.* [6] and briefly introduced in Section II A, as the parent Webworld model, and the model variant developed in this paper as the stochastic Webworld model. The term Webworld by itself refers to features generic to both.

A. Webworld

The Webworld model consists of dynamics on three separated time-scales, of which the longest corresponds to the introduction of new species. A detailed description of the parent model can be found in Drossel *et al.* [6]. In the present paper we do not consider the introduction of species through evolution, but instead examine two types of system. In the first, an existing community, constructed in the parent model, is interpreted in terms of discrete populations, and the evolution of the stochastic population dynamics is examined. In the second type of numerical experiment, we use a large community assembled in the parent model as a species pool, from which individuals are drawn during the construction of an immigrant community, in which the population dynamics are again stochastic. The subsequent discussion of the parent model will only restate those features of the parent model which are necessary to construct this non-evolutionary stochastic model.

Interactions between species in the Webworld model are governed by two evolved matrices, scores S and competition α. Each pair of species i, j has an associated score $S_{ij} = -S_{ji}$ describing the ability of one species to feed on the other. A positive value of S_{ij} indicates that species i is able to feed on species j, larger values corresponding to preferred prey. The anti-symmetric nature of the matrix S thus precludes mutual feeding and cannibalism. The competition matrix, α, describes the degree to which species compete with one another when feeding on the same food sources; this is described by a symmetric matrix, which has a minimum value of 0.5 for highly distinct species and a maximum value of 1 for intra-specific competition. In the parent Webworld model S and α are derived by an intricate system of evolution, but it has also been demonstrated [22] that varied communities can be assembled by immigration from an evolved species pool.

The intermediate timescale of the Webworld model corresponds to the population dynamics. By encapsulating the per-capita income of species i from prey species j in the functional response, g_{ij}, the rate at which the population of each species i changes is described by

$$\dot{N}_i = \lambda \sum_j g_{ij} N_i - \sum_j g_{ji} N_j - d N_i, \tag{2}$$

where the first term corresponds to the gain of resources through feeding, the second term corresponds to losses to predation, and the final term relates to the death of individuals through other processes. Webworld equates energy resources to population, equivalent to an assumption of equal body size for all individuals. In these terms, the ecological efficiency, $\lambda = 0.1$, which appears in the first term of (2), corresponds to the fraction of prey resources which can be converted into new predator individuals.

The shortest time-scale of the Webworld model relates to the adaptation of the functional response to changes in population. Part of this response is a direct consequence of the reduction in the prey density, which reduces the rate at which individuals can be found. The functional response also incorporates adaptation by foragers, who select prey to maximize their income. It is assumed that species as a whole rapidly respond to changes in the relative abundance of their prey and of their competitors. Section II E discusses an alternative method we consider by which the evolutionarily stable foraging strategy can be identified, but an ecologically plausible mechanism is likely to require an agent-based and spatial model, which will provide a mechanism capable of reproducing the functional response. The exact form of the functional response as used by Webworld is

$$g_{ij} = \frac{f_{ij} S_{ij} N_j}{b N_j + \sum_k \alpha_{ik} f_{kj} S_{kj} N_k}, \tag{3}$$

which uses the scores, S, and competition, α, already described. The term b in the denominator limits population growth for predator i of species j when $N_j \gg N_i$, whereas the sum limits the population of competing predators when their population is non-negligible. The term f_{ij} represents the fraction of its time that predator i spends feeding on prey species j, and was demonstrated by Drossel *et al.* [6] to have an evolutionarily stable strategy given by

$$f_{ij} = \frac{g_{ij}}{\sum_k g_{ik}}, \tag{4}$$

which can be found by iteratively solving (3) and (4).

B. Target reaction scheme

An essential modification made to the population dynamics in creating this stochastic model is the division of each species into hungry individuals, who are actively involved in feeding, and sated individuals, who are not. This standard assumption is used to derive a functional response in which the predation rate for high prey abundance has a limiting value [for example 23]. An important consequence of this division is that the rate of predation is not dependent on the total abundance of the predator, but of its hungry members. As prey become more numerous, it should be expected that a smaller fraction of the predator individuals remain hungry, and the predation rate per predator individual becomes restricted. This behaviour replicates an essential feature of the Webworld functional response.

Having identified the need to divide species into hungry and sated individuals, it follows from (2) that four generic reactions are required. The first term in (2) corresponds to feeding, and hence to the reaction

$$\mathrm{X}'_\mathrm{i} + \mathrm{X}_\mathrm{j} \xrightarrow{k_1} \mathrm{X}^*_\mathrm{i}, \tag{II}$$

where X'_i and X^*_i indicate an hungry and a sated individual of species i respectively, X_j is any member of species j, and reaction rate coefficient k_1 remains to be deduced. To restore individuals to the hungry state it is necessary to introduce the reaction

$$\mathrm{X}^*_\mathrm{i} \xrightarrow{k_2} \mathrm{X}'_\mathrm{i}, \tag{III}$$

since no interaction is expected to be necessary for sated individuals to become hungry. To enforce the principle of energy conservation not only on average, but in the details of the reaction scheme, reproduction can be supposed to occur only after feeding, and to be limited to one reproduction event per prey individual consumed. This suggests an analogy to [III],

$$\mathrm{X}^*_\mathrm{i} \xrightarrow{k_3} 2\mathrm{X}'_\mathrm{i}, \tag{IV}$$

where a sated individual of species i produces a hungry individual while becoming hungry itself. To complete the set of processes associated with (2) reactions corresponding to death are required. If death is equally likely to occur whether an individual is hungry or sated, the reaction can be written as

$$\mathrm{X}_\mathrm{i} \xrightarrow{d} \emptyset, \tag{V}$$

noting that, as with the prey individual in [II], [V] applies to both hungry and sated individuals.

C. Minimal reaction scheme

To help deduce the reaction rate coefficients for the reactions in Section II B, this section considers the simple scenario of a single species, i, feeding on a resource of fixed abundance R. The expected rate of change of abundance of hungry individuals can then be written

$$\dot{N}_{i'} = -k_1 N_{i'} R + k_2 N_{i^*} + 2k_3 N_{i^*} - dN_{i'}, \tag{5}$$

where the four terms correspond to the four reactions in Section II B in the order they appear. $N_{i'}$ and N_{i^*} are the hungry and sated populations respectively, which sum to give the total population, N_i. Correspondingly, the number of sated individuals changes as

$$\dot{N}_{i^*} = k_1 N_{i'} R - k_2 N_{i^*} - k_3 N_{i^*} - dN_{i^*}, \tag{6}$$

with the population of the species as a whole changing according to the sum of (5) and (6),

$$\dot{N}_i = k_3 N_{i^*} - dN_i. \tag{7}$$

The simplified version of (2) appropriate to this scenario, using (3) for the functional response, is

$$\dot{N}_i = \frac{\lambda S_{i0} R}{bR + S_{i0} N_i} N_i - dN_i, \tag{8}$$

where the fixed resources have been identified as species 0, and $f = 1$ occurs since no choice of prey is available. As described in Section II A, $\alpha = 1$ for all intra-specific competition.

Progress can be made by finding an appropriate steady state by which to eliminate time derivatives. By assuming the population of full individuals, N^*_i, to be a constant, (6) becomes,

$$N_{i^*} = \frac{k_1 R}{k_1 R + k_2 + k_3 + d} N_i, \tag{9}$$

allowing us to eliminate from (7) the population of sated individuals. This leaves

$$\dot{N}_i = \frac{k_1 k_3 R}{k_1 R + k_2 + k_3 + d} N_i - dN_i, \tag{10}$$

which has obvious similarities to (8). Assuming that the k values do not depend on R, it follows that

$$k_3 = \frac{\lambda S_{i0}}{b}. \tag{11}$$

Losses to the resources through [II] occur at rate

$$k_1 N_{i'} R = \frac{k_2 + k_3 + d}{R + \frac{k_2 + k_3 + d}{k_1}} R, \tag{12}$$

and according to the Webworld model at rate $S_{i0} R/(bR + S_{i0} N_i)$. In the limit of large R it follows that

$$k_2 + k_3 = \frac{S_{i0} - bd}{b}. \tag{13}$$

Because S_{ij} is typically of order 10 for active feeding links whilst $bd = 1/200$, we neglect the latter term in the numerator of (13) to obtain

$$k_2 = (1 - \lambda) \frac{S_{i0}}{b} \tag{14}$$

The fact that the rate coefficients of reactions [III], [IV] and [V] do not depend on any population implies that sated individuals can be considered as non-interacting entities. An implication of this in terms of predation is discussed in Section II F. Of all occurrences of reactions [III] and [IV], a fraction λ result in reproduction, in line with the ecological efficiency of the parent model. The reaction rate of the predation reaction is not so trivial, being given by

$$k_1 = \frac{1}{N_i}; \tag{15}$$

intra-specific competition causes the feeding rate of each member of the species to decrease in proportion to the total population, not merely the hungry population who are concurrently foraging. Section II D examines how this rate generalises to include inter-specific competition, and the effect of a diversified foraging strategy in reducing the intra-specific competition implied by (15).

D. Foraging strategy and competition

The generalisation of the reaction rate of predation must consider the effects of intra- and inter-specific competition. In the Webworld model, species adopting a mixed foraging strategy increase their reproduction rates by utilising more food sources, which is mathematically described by the reduction in intra-specific competition. Multiple predator species feeding on one prey are taken to be more effective at extracting resources from that prey species than a single predator species due to differences in strategy, and hence inter-specific competition is somewhat less detrimental than intra-specific competition. The effect of a mixed strategy by a single predator species will be considered first. The optimal strategy, f, used by Webworld is the evolutionarily stable strategy (ESS); an individual cannot increase its reproductive success by adopting any other foraging strategy. Given the implication of the analysis in Section II C that the probability of reproduction by a sated individual is λ, and hence independent of its food source, it follows that the optimal strategy for a hungry individual also corresponds to minimising the time before next becoming hungry. In general this time depends on the prey species chosen by an individual, and we write as τ_{ij} the expected time before a hungry individual of species i, following a pure strategy of feeding on species j, next becomes hungry. For an optimal strategy τ_{ij} is independent of j, and hence no individual can improve its reproduction rate by changing strategy. Importantly, this condition is not the same as minimising the time before next feeding, since the expected time in the sated state is

$$\tau^*_{ij} = \frac{b}{S_{ij}}, \tag{16}$$

which is smaller for prey species corresponding to large S_{ij}.

Inspection of the Webworld functional response, (3), demonstrates that a single species following a mixed strategy consisting of two prey has instantaneous population growth equivalent to considering two populations following pure strategies, where the sub-populations are given by $N_{ij} = f_{ij} N_i$. In the absence of both inter-specific competition and predation, and denoting the prey as species 1 and 2, the total population growth is given by

$$\begin{aligned} \dot{N}_{i1} + \dot{N}_{i2} \; &= \; \frac{\lambda S_{i1} N_1}{bN_1 + S_{i1} N_{i1}} N_{i1} \\ + \frac{\lambda S_{i2} N_2}{bN_2 + S_{i2} N_{i2}} N_{i2} \; &- \; dN_{i1} - dN_{i2}, \end{aligned} \tag{17}$$

which is equivalent to treating components N_{i1} and N_{i2} as separate species following pure strategies. In terms of the stochastic model, it follows that N_{i1} is the total number of individuals either foraging for prey 1 or sated having eaten that prey, and hence we can write

$$f_{ij} N_i = \phi_{ij} N_{i'} + N_{i^*j}, \tag{18}$$

where ϕ is the foraging strategy of hungry individuals and N_{i^*j} is the number of individuals of species i sated by having consumed a member of species j. The dependence of (18) on N_{i^*j} can be eliminated by considering the balance of reactions affecting the population of sated individuals in the steady state, where

$$\frac{N_j}{f_{ij} N_i} \phi_{ij} N_{i'} = \frac{S_{ij}}{b} N_{i^*j} + dN_{i^*j}. \tag{19}$$

The left hand side of (19) represents the rate at which foraging individuals become sated, the terms on the r.h.s being the sum of hungering and reproduction, and death. Using (18) to eliminate N_{i^*j} from (19), the foraging strategy of hungry individuals is found to be given by

$$\phi_{ij} = \frac{N_i}{N_{i'}} \left\{ 1 + \frac{bN_j}{(S_{ij} + bd)\, f_{ij} N_i} \right\}^{-1} f_{ij}. \tag{20}$$

We note that, subject to the condition that $S_{ij} \gg bd$, (20) can be written as

$$\phi_{ij} = \frac{f_{ij} S_{ij} N_j}{bN_j + f_{ij} S_{ij} N_i} \frac{N_i^2}{N_{i'} N_j} f_{ij}, \tag{21}$$

where the first fraction is exactly the form of g_{ij} in the parent Webworld model. Thus, in the absence of inter-specific competition, the rate of feeding through [II] is given by

$$k_1 N_{i'} N_j = \frac{\phi_{ij} N_{i'} N_j}{f_{ij} N_i} = g_{ij} N_i. \tag{22}$$

The appropriate foraging strategy for hungry individuals can be calculated using (20), and (22) demonstrates that this results in dynamics consistent with the parent model.

The reaction rate given by (22) needs to be modified in the presence of inter-specific competition. By noting the argument associated with (17), that species pursuing a mixed strategy can without loss of generality be split into species of pure strategy, it is possible to deduce the form of (22) for competition without strategy, and hence infer the behaviour of the system when both competition and strategy are allowed. First we equate the population growth equations of the parent and stochastic Webworld models for species i feeding on prey species j,

$$\frac{\lambda S_{ij} N_{i^*j}}{b} - dN_{ij} = \frac{\lambda S_{ij} N_j N_i f_{ij}}{bN_j + \sum_k \alpha_{ik} f_{kj} S_{kj} N_k} - dN_{ij}; \tag{23}$$

this can easily be simplified because the death terms and ecological efficiency appear equivalently on both sides. In steady state the number of sated individuals, N_{i^*j}, can be found by setting the population growth of strategy i, j to zero, and hence

$$k_{ij} \left(f_{ij} N_i - N_{i^*j} \right) N_j = \frac{S_{ij} + bd}{b} N_{i^*j}, \tag{24}$$

where k_{ij} is the rate coefficient for the feeding reaction, [II], and the r.h.s. is the total rate at which the number of sated individuals is reduced. Rearranging (24) in terms of the fraction $N_{i^*j}/f_{ij}N_i$ gives

$$k_{ij} N_j = \frac{S_{ij} + bd}{b} \left\{ \frac{f_{ij} N_i}{N_{i^*j}} - 1 \right\}^{-1}. \tag{25}$$

This ratio can also be obtained from (23), from which we obtain

$$\frac{f_{ij} N_i}{N_{i^*j}} = \frac{bN_j + \sum_k \alpha_{ik} f_{kj} S_{kj} N_k}{bN_j}. \tag{26}$$

Substituting (26) into (25) gives

$$k_{ij} = \frac{S_{ij} + bd}{\sum_k \alpha_{ik} f_{kj} S_{kj} N_k}, \tag{27}$$

which is similar in form to (3). If we again assume that $S_{ij} \gg bd$, this can be written

$$k_{ij} = \left\{ \sum_k \alpha_{ik} f_{kj} \frac{S_{kj}}{S_{ij}} N_k \right\}^{-1}, \tag{28}$$

and is clearly seen to simplify to (15) for a pure strategy in the absence of inter-specific competition, where $\alpha_{ii} = 1$. For the case in which a single predator has reduced intra-specific competition due to adoption of a mixed strategy, (28) gives

$$k_{ij} = \frac{1}{f_{ij} N_i}, \tag{29}$$

where the appropriate forager and prey populations are $\phi_{ij} N_{i'}$ and N_j respectively, giving (22).

It is now possible to demonstrate that the ESS of the parent model corresponds as expected to the optimal individual behaviour, which minimises the time until next becoming hungry, when reproduction might occur. For species i feeding on prey species j this time is

$$\tau_{ij} = \frac{\sum_k \alpha_{ik} f_{kj} S_{kj} N_k}{S_{ij} N_j} + \frac{b}{S_{ij}}, \tag{30}$$

where the first term is the reciprocal rate of feeding, and the second is the reciprocal of the total rate of hungering and reproduction. Given the definition of g in (3), it is clear that

$$\tau_{ij} = \frac{f_{ij}}{g_{ij}}. \tag{31}$$

For the ESS, the foraging strategy f is related to the functional response g by

$$f_{ij} = \frac{g_{ij}}{\sum_k g_{ik}}, \tag{32}$$

and hence the expected time for an individual of species i to next become hungry is given by

$$\tau_{ij} = \left\{ \sum_k g_{ik} \right\}^{-1}, \tag{33}$$

which is independent of prey as expected.

E. Variants

Two basic variations of the stochastic Webworld model are suggested by the details of the behaviour seen above, which relate to anti-predator behaviour and to decision making. Having shown that the rate coefficients of [II] and [III] should be independent of population, it follows that sated individuals are in no way influenced by the population of their own species or of prey, and to some degree can be said to be isolated from the community for the period of time they remain sated. It is reasonable to assume that for real animals subject to this condition, this period of time would be best spent in a den or other refuge offering relative safety from predation. Regardless of the means by which such safety might be effected, which is more properly the concern of an agent-based model using spatial and individual-rationality considerations, we consider it proper to examine whether the vigilance of sated individuals has significant consequences for the model dynamics. We therefore denote as variant a of the model the case in which sated individuals are equally susceptible to predation as foraging individuals, and as variant b the case in which sated individuals cannot be predated at all. If it can be demonstrated that no significant differences exist between these two cases, it is to be expected that reasonable intermediate cases can also be unproblematically related to the parent model. In so far as it makes no difference to the dynamics, we prefer to adopt variant b as the default case, since this suggests a more optimal individual behaviour.

In the parent model, foraging strategy is taken to adapt to the current population of all species on the shortest possible time-scale, so that at all times all individuals of all species follow the evolutionarily stable strategy, which is computationally arrived at by considering the effects on (3) of prey availability and competitor abundance. A more plausible model of strategy selection would incorporate at least the effects of limited knowledge, since individual predators must make decisions based on observation or communicated information rather than directly based on global population data. Such decision making is also likely to be based on spatial distribution, and we therefore defer both informational and spatial considerations to the agent-based model we foresee as the next development of Webworld toward an ecosystem model grounded in individual-level considerations. For the purposes of this paper we consider a method of strategy selection such that the eventual, detailed behaviour model is likely to lie within the range investigated here. Variant I denotes the case in which each time the population of any species changes, the strategy of each species is updated, and all individuals follow the ESS. For variant II we attempt to recover the ESS through population dynamics. In this case we assign to each individual a prey species which is their only prey for life, and are able to approximately track the ESS by causing offspring to adopt the same foraging strategy as their parent. Strategies which are under-represented in the population of a species have a higher reproduction rate than strategies which are over-represented, leading to their replenishment and convergence toward the ESS. A complication is that the population of each strategy is subject to demographic stochasticity, and hence at risk of extinction. With probability μ we assign each newborn individual to a strategy selected at random using the contemporary ESS as a probability distribution. This allows extinct strategies to be repopulated without losing large numbers of individuals to unviable strategies. We investigate the results for μ in the range $0.01 \leq \mu \leq 1$, and use $\mu = 0.1$ as the standard value.

F. Summary

The implementation of the stochastic Webworld model requires that each species, population N_i, be divided into sub-populations according to the number of prey it possesses. The number of individuals actively foraging is given by $N_{i'}$ while the sated individuals are divided into groups according to the last prey item consumed, with populations N_{i^*j}. Sated individuals return to the foraging population at a rate dependent on the prey species consumed, returning more rapidly for prey species corresponding to a large score, S_{ij}. In variant I foraging effort is divided in the same manner as in the parent model, according to the evolutionarily stable strategy (ESS) given by (20). In the more stochastic variant II each individual pursues a single prey species, and the relative reproductive success of different foraging strategies contributes to the identification of the ESS by natural selection. For small forager populations it is necessary to avoid the permanent extinction of strategies by allowing mutant offspring to follow a strategy different from that of their parent, which occurs with probability μ.

The second variation in the stochastic model that we consider is the ability to feed on sated individuals. It is implicit in the deterministic population dynamics that all individuals of a species are equally vulnerable to predation, but as shown in Section II C, sated individuals are not influenced by any other individuals of their own or prey species. Following such work on optimal strategies as Houston *et al.* [24], it may be reasonable to assume that individuals not engaged in foraging are able either to seek refuge where they are not vulnerable to predators or to adopt some vigilance strategy that removes the risk of predation at the expense of being unable to simultaneously forage. This being the case, and noting that at the steady state the fraction of sated individuals is

$$\frac{N_{i^*j}}{N_{ij}} = \frac{bN_j}{bN_j + \sum_k \alpha_{ik} f_{kj} S_{kj} N_k}, \tag{34}$$

which is typically of the order 10^{-2} for $N_{\text{prey}}/N_{\text{predator}} \sim 10$ and $S \sim 10$, it is not strongly disruptive to the model to assume that only hungry individuals are susceptible to predation. Because we believe it to have the most plausibility, and most potential for developing a more detailed model, we use variant IIb as the default model against which others are compared.

III. RESULTS BY PHENOMENOLOGY

In order to compare the newly developed stochastic model with the parent model as closely as possible, we contrast their behaviour in three sets of circumstances. Each of these utilises the same ‘mainland’ community of species, evolved in the parent model and containing 103 species, in order that incidental differences are minimised. The simplest comparison between the parent and stochastic models is to directly compare the population dynamics, for which purpose it is preferable to make use of a food web of fewer species and lesser complexity than the mainland. Powell & McKane [22] introduced the method of using an evolved Webworld ecosystem as a species pool from which an ‘island’ community could be assembled by the addition of many species under the action of the population dynamics. Two small webs which resulted from this process, which we refer to as Islands A and B, are drawn in Table I, and were used to study the population dynamics in the absence of the introduction of any further species. These results were repeated for several other webs of differing size as a test of generality. The labels associated with species indicate their trophic level, so species P1 is a ‘plant’, H1 a ‘herbivore’, and C1 a ‘carnivore’. Species E is the environment, population R, which provides a constant food source for all plants.

Island A consists of two herbivore each feeding predominantly on pairs of plants. However, the most populous herbivore focuses some feeding attention on plant P1 and also directly on herbivore H1	Island B is already a highly complex web with interesting adaption to increasing stochasticity. The omnivory of the carnivore and herbivore H2 are not seen in the parent model.	
TABLE I: The food webs used in the comparison of time-series between the stochastic and parent population dynamics. In all webs, solid lines remain over all scalings. Long, medium and short dashed lines are those which are intermittent at $\Omega = 10$, $\Omega = 30$ and $\Omega = 100$, respectively. The green arrows show intermittent links which exist only in the stochastic dynamics and are not represented in the parent model at all. The species designations are given in ascending order of population in the parent model.

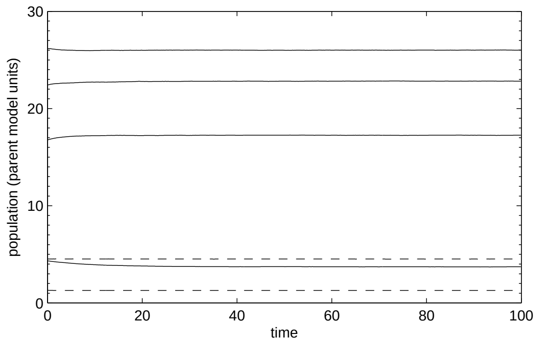

FIG. 1: The ensemble mean of time series generated with the stochastic population dynamics for Island A, using variant IIb with $\mu = 0.1$ and scaling $\Omega = 300$. Population sizes are divided by Ω for comparability. Solid lines mark species on the lower trophic level ('plants'); dashed lines mark species on the upper trophic level ('herbivores').

The second comparison of the two models is to create communities directly in the stochastic model. Because island creation restricts the set of species to those present in the mainland community, the results are more directly comparable than are those for independently evolved communities, and the process of immigration produces mature communities much more rapidly than is achieved by evolution from a single ancestral species. As such, the second test of the similarity of the two models was performed by statistical comparison of islands constructed under the two types of population dynamics. A third test, referred to as the 'reduction' process, is to take a large food web and record its behaviour as the resources supplied to basal species, R, are reduced. Using the mainland community as the initial food web, reduction of R tends to reduce the population of each species by the same factor until one or more species go extinct. Because the food web structure changes at this point, the subsequent behaviour of the food web is not trivially predictable. Under the population dynamics of the parent model the reduction process follows a deterministic trajectory, which can be compared to an example trajectory derived from the stochastic model.

A simple feature of Webworld, which arises from the use of a ratio-dependent functional response, is that the dynamics of the parent model are completely unaltered if the basal resources, R, the population at which species go extinct and the population of each species are all scaled by the same factor. Equations (2) and (3) show that, once scaling is taken into account, the population dynamics of the system is unchanged. In the parent model it is therefore reasonable to set the scale by assigning the extinction threshold to a population of unity, but this does not necessarily correspond to one individual of the stochastic model. When comparing simple population dynamics with the parent model, we therefore adopt a scaling factor, Ω, by which populations from the parent model are multiplied to obtain starting populations for the stochastic model. The results presented in Figs. 1, 2, 6, 8 and 10 are divided by the same scaling factor to assist comparison. The largest value of scaling adopted is $\Omega = 300$, which is a limitation of computational resources. The smallest value, $\Omega = 10$, is a consequence of the large fraction of simulation runs in which at least one species goes extinct within the first one hundred units of time, and suggests that the minimum viable population on this time scale is of the order ten. When considering island or reduction results, it is no longer appropriate to refer to a scaling, since species are removed from the community by extinction by fluctuations about an unknown typical minimum population. Instead, Figs. 9 and 11 use the number of species present as a proxy for food web size when comparing other food web attributes between the parent and stochastic Webworld models.

Having introduced variant II, in which the foraging strategy adopted by a species is not the evolutionarily stable strategy (ESS) but rather a collective strategy based on each individual feeding on a single prey species, it is important to assess the effect of choosing different values of the mutation probability, μ. The demographic extinction of certain strategies is inevitable if inheritance is important, and even when $\mu = 1.0$ individuals retain a single strategy for their entire life-span, restricting the ability of the strategy of the species as a whole to adapt to the contemporary ESS. We therefore consider the ef-

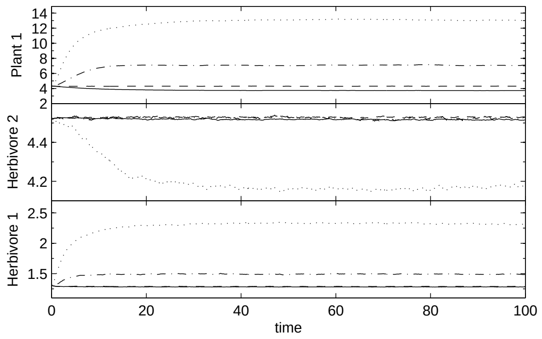

FIG. 2: Selected species from Island A showing the effect of reducing the scaling from $\Omega = 300$ (solid) through $\Omega = 100$ (dashed) and $\Omega = 30$ (dot-dashed) to $\Omega = 10$ (dotted). Note that the y-axes are independently scaled and also overlap with each other.

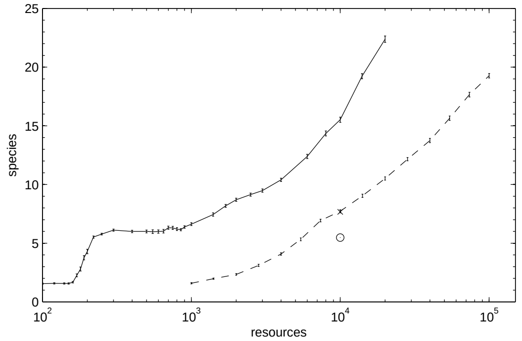

FIG. 3: The mean number of species for an ensemble of one hundred islands, against resources. Solid line; parent model. Dashed line; variant IIb with $\mu = 0.1$. Cross; variant IIa with $\mu = 0.1$. Circle; variant Ib.

fects of five values of μ, spaced logarithmically in the range $0.01 \leq \mu \leq 1.0$, to which we add variant Ib as a comparable variant in which the ESS is followed at all times.

The following three sections concentrate on three phenomena by which the parent and stochastic models can be compared. In Section III A we examine how the parent model differs from the ensemble average of results from the stochastic model. In Section III B we examine the nature of the fluctuations about the ensemble average seen in any given realisation of the stochastic model, and use these insights to understand some attributes of the webs persistent under the stochastic dynamics. In Section III C we consider in detail the effects of using variant IIb, in which links between species are formed and broken through the population demographics.

A. Recovery of the parent model

The ensemble-average time series from the stochastic dynamics in Island A at $\Omega = 300$ and $\mu = 0.1$ is reproduced in Fig. 1. Apart from the least populous plant, the ensemble average population of each species reaches a fixed point by the mid-point of the time-series which differs by less than 3% from that of the parent model, which is the initial condition. The discrepancy relates to the extent to which variant IIb is able to sustain those weak links which have been shown by McCann [25] to have an important influence on food web structure. No extinctions were observed for this value of Ω, and excellent agreement with the parent model is achieved for modest population sizes - each species present has a population of less than ten thousand individuals.

For smaller values of Ω, the influence of demographic stochasticity is more pronounced. Not only do weak links become more susceptible to disruption, but species as a whole are more vulnerable to extinction. In order to understand a homogeneous data set we average over only those simulation runs in which extinction did not occur. Ensemble averages of the population dynamics, corresponding to Fig. 1, are shown in Fig. 2 for the three species which showed significant deviation from the steady-state population found in the parent model. The probable cause of the deviations from the parent model result is the change in the food web structure as weak links are removed, and is discussed in detail in Section III C. The qualitative effect is that as smaller values of Ω are considered, the parent model fails to reflect even the ensemble average of the population dynamics. The important influence of weak links on the food web structure is intimately connected with the population dynamics, since a weak link implies an event of rare occurrence whether or not the species involved are of small population. The ensemble average for small Ω can be recovered in the parent model by specific selection of which links need to be incorporated, but this process cannot be properly understood without first assessing the results of the stochastic model.

The corresponding result for the island model is shown in Fig. 3, in which the number of species in a mature island community is shown for both the parent model and variant IIb of the stochastic model. The first point of agreement with the population dynamics results is that there exists an approximate factor of ten between the resources necessary to produce comparable results in the two models; if the curve for the stochastic dynamics is shifted a decade to the left, it approximately overlays the parent model results. In particular it is notable that complex communities are still readily formed by immigration under stochastic population dynamics, the largest communities constructed being limited by computational resources rather than intrinsic properties of the model. Noting that these results correspond to the Type IV species-area curve of Scheiner [26], which relates to the number of species in distinct islands and is therefore not necessarily monotonic, there is a good overall agreement about the increase in species number with resource availability, which we equate to the physical ex-

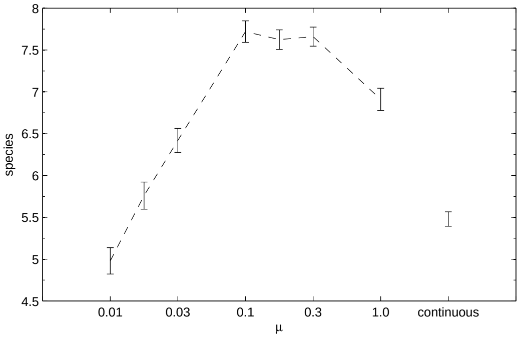

FIG. 4: The mean number of species for an ensemble of one hundred islands against mutation probability μ, for $R = 10^4$. The dashed line connects points belonging to variant IIb; the final, disconnected point corresponds to variant Ib and hence is not part of the same interpolation.

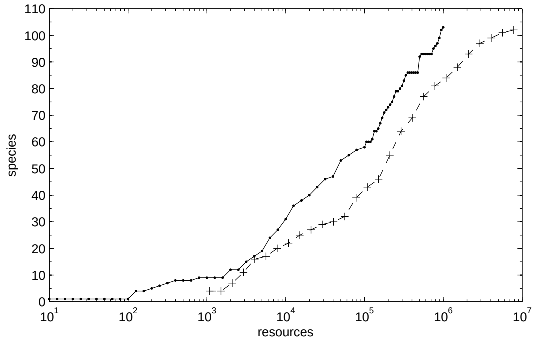

FIG. 5: The number of species remaining as resources are reduced, against resources. Solid line; parent model with slow reduction. Dashed line; variant IIb with $\mu = 0.1$, reducing resources by 8% in unit time, compared with $d = 1$.

tent of a real ecosystem. The most significant deviation corresponds to communities at the smallest values of resources, where there is a step-like transition in the case of the parent model from systems with one or two species to those with several. This phenomenon was discussed in Powell & McKane [22], and is caused by the weakening of niche-sharing restrictions on plants when one or more herbivores enter the system. In the case of the stochastic population dynamics there is no noticeable step, and examination of numerous example food webs indicates that even when herbivores become viable, it remains difficult to sustain multiple plant species. The underlying cause of the continued exclusion under stochastic dynamics is explored in Section III B. The circle in Fig. 3 marks the number of species present when variant Ib is used rather than variant IIb, and there is consequently no selection against weak links. The result is that fewer species are able to co-exist, a consequence of the improved ability of herbivores to exploit relatively rare plant species. Fig. 4 shows how the number of species simultaneously sustained for this value of resources, $R = 10^4$, varies with the ability of species to adopt new strategies though changing mutation, μ. The point corresponding to variant Ib does not properly belong on the same scale as different values of μ, but conceptually corresponds to a situation of very large mutation rate and is therefore plotted to the right of the figure. It is notable that there exists a peak in the number of species, where small values of μ do not allow sufficiently diverse strategies to maximise the species diversity, but large values of μ also reduce diversity through the ease of resource exploitation, indicating a positive relationship between specialisation and diversity for this region of parameter space.

A further check on the ability of the stochastic population dynamics to support complex food webs is supplied by the reduction scenario. Fig. 5 shows the path that a single stochastic realisation of the reduction of resources follows, along with the unique path followed by the parent model. Similarly to the island results, there is approximately a factor of ten in resources between the two curves, although this is partially obscured by the rapid rate at which it was necessary to constrict resources for the stochastic model. Whereas the population dynamics of the parent model can be run such that resources are reduced at an effectively infinitesimal rate, computational requirements and practical considerations require the stochastic model to be run at a definite reduction rate. Computing the population dynamics of any community under stochastic population dynamics for an infinite length of time without speciation will result in the extinction of every species through fluctuations, so there does not exist an asymptotic curve for the stochastic model. Furthermore, the slowest rate of restriction for which results could be simulated corresponds to an 8% reduction in resources per unit time period, which is rapid given that the expected lifetime of an individual is also unit time. Species are therefore expected to persist to smaller values of R under these circumstances than would be true for a slower reduction rate, and the curve is somewhat smoothed by the stochastic delay introduced between the time a species becomes unviable and the moment at which it becomes extinct. Allowing for this effect, there is good agreement between the two curves, and the stochastic model is shown to be successful at allowing large, complex communities to persist.

B. Fluctuations and intra-trophic neutrality

One way in which the stochastic model differs from the parent model is that fluctuations in population sizes exist even when the ensemble average populations are constant. Extinction occurs when the fluctuating population of a species drops instantaneously to zero, and hence the relative magnitude of fluctuations is an important contributing factor to food web structure. In this section we examine the variance of those fluctuations, and the extent to which the fluctuations in different species are not independent. Fig. 6 shows that, even for scaling

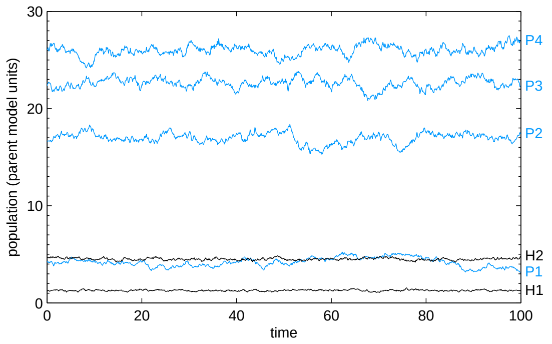

FIG. 6: The time series of one realisation of the stochastic population dynamics for Island A, using variant IIb with $\mu = 0.1$ and scaling $\Omega = 300$. Blue lines; plant species. Black lines; herbivores.

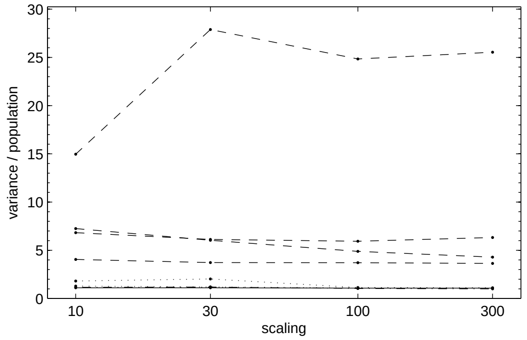

FIG. 7: The ratio of the variance of population time series to the mean population at various values of scaling, Ω. Dashed lines; plant species. Dotted lines; herbivore species. Solid line; total plant population. Dash-dotted line; total herbivore population.

$\Omega = 300$, these fluctuations are of significant amplitude, and it is notable that despite the similarity in population size, plant P1 exhibits significantly larger fluctuations than herbivore H2. Fig. 7 shows the variance of each of the species averaged across an ensemble for each of the scaling factors, Ω, examined. In every case the variance for plant species is larger than that for the herbivores, the more populous of which has a variance nearly equal to its mean population for all values of Ω used. For the larger values of Ω the variance is approximately proportional to the population for all species, and hence the lines in Fig. 7 are approximately horizontal. This indicates that as the scaling factor increases, the standard deviation of population size increases only as the square root of the population. The ability to neglect fluctuations for very large population sizes is an assumption implicit in the parent model, and these results demonstrate that the fluctuations do indeed become negligible.

If time series subject to independent noise are added, the variance of the summed time series is equal to the sum of the variance of each time series separately. The relative variance would therefore lie between the values calculated for each time series, yet Fig. 7 clearly shows that this is not the case for the stochastic Webworld results. Indeed, the variance for the sum of the plant populations is nearly equal to the total population, as is also the case for the sum of herbivore populations. This indicates that the fluctuations in the plant populations must be anti-correlated. In Fig. 8 a time series for plant P4 is shown along with that for the sum of the other three plants. It can be seen that significant anti-correlation does exist, which is especially obvious for the large fluctuations around time 55 and 70. To quantify this relationship we calculate the correlation coefficient, r^2, between time series [27]. It was found that an increase in r^2 could be found by allowing a offset between the time series of different species, and Table II records the maximum value of r^2 and the corresponding time offset, along with the gradient of the best-fitting regression line. The results show that for Island A two pairs of plants exist with relatively strong correlation; species P1 correlating strongly with P3, and P2 with P4. As shown in Table I, these pairs form trophic species in the full sense that they share both food source and predators, although P1 is also weakly predated by H2. These trophic species are strongly correlated with each other, and are more strongly correlated their respective herbivores than is any individual plant species. The optimal time offset for any pair of species within the same trophic level is near zero, while the best correlation between the trophic plants and herbivores is found with the herbivore time series lagging by up to approximately unit time, suggesting that changes in the herbivore population can, in part, be attributed to fluctuations in the abundance of their food source. The gradient of the regression line between each pair of plant species is close to -1. This is a consequence of the strong competition between species which share a common food source. Although the total population across all plant species is relatively well-constrained, any one plant species can increase in population at the expense of it competitors. Meanwhile there is a positive correlation between the population of each herbivore and that of the trophic species upon which it predominantly feeds. With the opposite gradient, there is a consequent correlation between herbivore population and the competitors of their prey.

A similar analysis was carried out with Island B, of which the results for the sub-web comprising P1, P2, H1 and H3 are particularly notable and are appended to Table II. Two major differences between this sub-web and Island A are the presence of stronger cross-links and the presence of the carnivore, making the combination of H1 and H3 a trophic species. As well as the correlation between plants, there is a significant correlation between herbivores, also with near-zero offset. However, although the optimal offset between herbivore and plant time series is of similar magnitude to those seen Island A, in Island B it is the herbivore populations which lead. The gradient in Table II is equal to the number of individ-

Island	x	y	r^2	Δt	gradient

	H1	H3	0.60	0.1	-1.0

TABLE II: Selected data from the analysis of correlations in both Islands A and B. The y-time series is offset by Δt with respect to the x-series to maximise the correlation coefficient, r^2. The gradient shown is that of the best-fitting regression line at Δt. Note that the typical population of species in Island B is greater than in Island A, contributing to larger values for r^2.

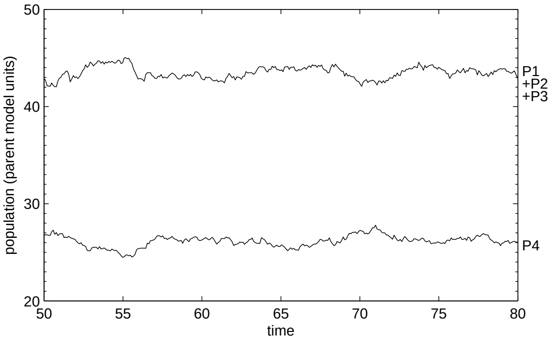

FIG. 8: An example of anti-correlations between populations of basal species, taken from Island A using variant IIb with $\mu = 0.1$, scaling $\Omega = 300$. The lower line marks the population of the most populous plant, P4. The upper line marks the total population of the other three plants.

uals of the plant species necessary to support a single extra herbivore. This number is greater in Island B due to the additional losses to predation by the carnivore, whose inclusion may be responsible for altering the relative strength of top-down and bottom-up effects, reflected in the change from lagging to leading herbivore fluctuations.

In the parent model, the co-existence of multiple species within a trophic species is allowed because inter-specific competition is less that intra-specific competition, encoded in the competition factor, α. This can be interpreted as reflecting differences in the feeding habits of competitor species which are not explicitly modelled. Under stochastic population dynamics an additional effect is observed in which demographic fluctuations in the populations of the niche-sharing species are larger than those of species which do not share a niche. By extension we expect that an increasing overlap of common predators and prey between two species corresponds to an increasing amplitude of fluctuations in population, while the total population of the niche (trophic species) remains relatively steady. As inter-specific competition increases, and $\alpha \to 1$, both the parent and stochastic models would predict the extinction of the less suitable taxonomic species within trophic species.

A consequence of the large fluctuations in the population of trophically similar species in the stochastic model is a stronger exclusion of niche-sharing species. In turn, fewer plants are able to co-exist in island communities. This is reflected in the reduced number of species present in stochastic islands relative to parent-model islands, as can be seen in Fig. 3. A further effect, shown by Fig. 9, is that the average number of trophic levels is higher in the case of the stochastic model than for the parent model when comparing webs with an equal number of species and no carnivores (approximately, $S < 10$). Since webs containing multiple plants and no herbivores are less stable under stochastic dynamics, it follows that for a given number of species there will be more webs with at least one herbivore.

C. Strategy extinction and web restructuring

Having introduced demographic effects into foraging strategy through variant II of the stochastic model, in which each individual feeds on a single prey species for its entire life-span, species become susceptible to ‘forgetting’ feeding links if the typical number of individuals following that strategy is small. As the scaling factor, Ω, is reduced, species become increasingly susceptible to this effect, and departures from the food web structure of the parent model are expected to increase in magnitude. The diagrams of the Island A and B food webs shown in Table I illustrate how weaker feeding links are successively lost as Ω is decreased from 300, when the webs are essentially equivalent to those in the parent model, through $\Omega = 100$, 30, and 10. Once a feeding link is removed from the model, the prey species typically increases in population and the predator decreases, since it is receiving income from fewer prey individuals. The context within the food web structure complicates this picture, since the removal of competition strengthens the ability of other predators to exploit a species. For example, if the link between P1 and H2 in Island A is lost, H1 does not suffer inter-specific competition when feeding on P1, and is therefore able to increase in population. This reduces the beneficial effect to P1 of this link being lost. A second example of the indirect consequences of the loss of weak links is provided by the cessation of feeding by H2 on H1. When this occurs H1 increases in population,

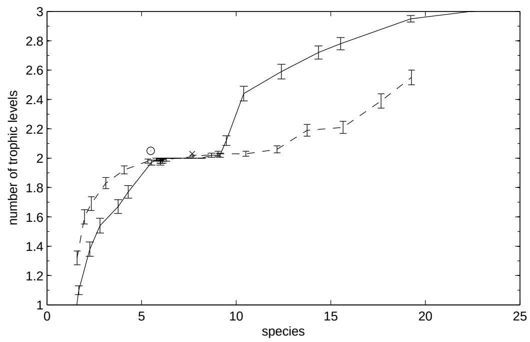

FIG. 9: The mean number of trophic levels against the mean number of species present, for an ensemble of one hundred islands at each point. Solid line; parent model. Dashed line; variant II*b* with $\mu = 0.1$. Cross; variant II*a* with $\mu = 0.1$. Circle; variant I*b*.

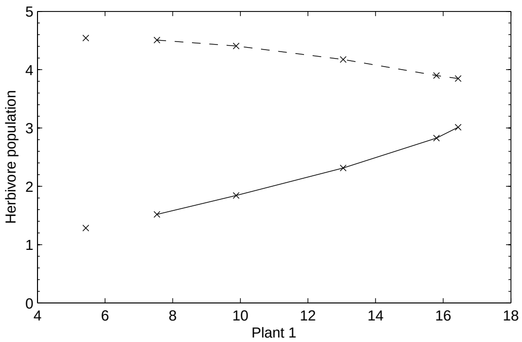

FIG. 10: Parametric plot of the population of plant P1 and the two herbivores of Island A, using variant II*b* with scaling $\Omega = 50$. From right to left the points correspond to $\mu = 0.01$, 0.03, 0.1, 0.3, and 1.0. The disconnected points to the left correspond to variant I*b*.

increasing the predation pressure on plants P1 and P3, whose populations decrease. The propagation of complex indirect effects through the food web can be understood in basic terms by investigation of the proximal effects of link removal, but the net effects on the community cannot be predicted any more simply than by directly simulating the population dynamics, due to the complex nature of competition and predation relationships.

In addition to the loss of weak links, some links appear in the stochastic model which would be predicted from the parent model to correspond to less than a single individual. For small values of Ω the food web structure has been changed by the deletion of other links, with the result that the populations of species differ from their values in the parent model. Under these circumstances links may become viable for one of two reasons; either the prey species has increased in abundance to the point at which it forms an exploitable resource, or competition for that prey has decreased. In general both of these effects occur, and several such links are marked on the diagram of Island B in Table I. All these links are intermittent - the predator species does not permanently have individuals which follow the strategy, but that sub-population goes extinct and is later re-established through the birth of a mutant individual. In the case of extremely simple food webs it can be seen that there are population changes in the prey species depending on whether or not it is being fed upon, but in even moderately complex food webs such effects are within the demographic noise and hence cannot be clearly demonstrated.

Fig. 10 demonstrates how the population of plant P1 increases with decreasing μ, which corresponds to an increase in the expected time before an individual of species H2 mutates to re-populate the extinct foraging strategy. Correspondingly, herbivore H2 is seen to decrease in population with decreasing μ, since this source of nutrients forms an increasingly small part of its diet. Herbivore H1, whose feeding link to P1 does not significantly decrease over this range of μ, experiences a population increase correlated with the increasing abundance of its prey. Because H1 does not feed exclusively on this plant, its population increase is smaller as a fraction of its total population than the increase in P1, which becomes an increasing fraction of its diet with increasing abundance. This figure demonstrates specific causes of both positive and negative correlations between populations, illustrating the complex outcomes of the food web dynamics.

The large-S part of Fig. 9 shows that the number of carnivores is less in the stochastic than the parent model when considering food webs with equal numbers of species, but that carnivores are not completely excluded from the food webs. The reduction in their prevalence is a consequence of the removal of weaker feeding links, since carnivores in the Webworld model tend to have more diverse diets than do lower trophic levels. As an example of this, the single carnivore in Island B feeds on each of the four herbivores, but no herbivore in the parent model (i.e. excluding shaded links in Table I) feeds on more than two species. Because the population required to sustain links to four prey species is greater than that necessary to feed on a single prey, the entry of carnivores into the food web is delayed relative to the entry of the lower trophic levels, and in particular it is possible to support a larger number of plant and herbivore species before carnivorous strategies become viable. As a consequence, the curve for the stochastic model lies below that for the parent model when considering trophic levels greater than two. The absence of these feeding links also increases the fraction of 'top' (unpredated) species, as shown in Fig. 11. For a small total number of species, S, the curves for the parent and stochastic models are very similar as only plants and herbivores exist, and despite differences in the proportion of species found in those two trophic levels as discussed in Section III B. The circle marks the point corresponding to variant I*b*, in which the presence of feeding links is not affected by demographic effects, and which as a consequence is within the region occupied by the parent model. The inset to Fig. 11 shows the monotonic de-

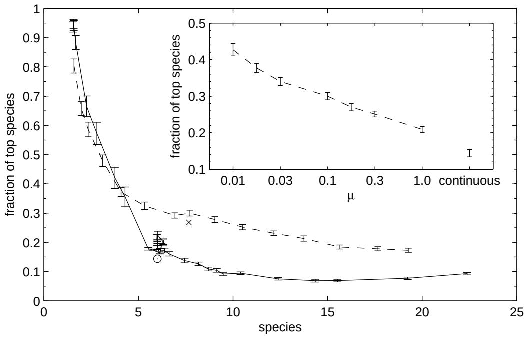

FIG. 11: The mean fraction of unpredated species against the mean number of species present, for an ensemble of one hundred islands at each point. Solid line; parent model. Dashed line; variant IIb with $\mu = 0.1$. Cross; variant IIa with $\mu = 0.1$. Circle; variant Ib. **Inset:** The mean fraction of unpredated species against mutation probability μ, for $R = 10^4$.

	Variant IIa		Variant Ib		Variant IIb

TABLE III: A comparison of stationary behaviour between variant IIa, in which all individuals are vulnerable to predation, and variant IIb, in which only hungry individuals are vulnerable, is shown for Island A. The scaling used here is $\Omega = 10$. μ; mean. σ; standard deviation.

crease in the fraction of top species as μ is increased, and the continuation of this trend into variant Ib.

D. Refuge for sated individuals

The distinction between variants a and b of the model corresponds to the ability of sated individuals, who cannot gain advantage from any interaction, to avoid interaction with predators. In variant b sated individuals are completely safe from predation, whereas in variant a they are as vulnerable as foraging individuals are. The plausible behaviour of a more detailed model is likely to lie between these two extremes. Table III records the ensemble average population for each of the six species of Island A for variants IIa and IIb, and variant Ib for comparison. The standard deviations, also shown, indicate the size of the population fluctuations. It is apparent that for each species the difference between variants IIa and IIb is much smaller than the corresponding fluctuations, but the differences between variants I and II are significant. These findings are reflected in the position of markers in Figs. 3, 9 and 11. In each case variant IIa produces results essentially equivalent to variant IIb, while variant Ib shows significant differences. In the latter two figures, where the number of species in an island food web is used to relate the size of parent-model and stochastic-model webs, variant Ib produces results similar to the parent model. If refuge has important consequences for food web structure then its effects are likely to be concealed within the functional response used by Webworld.

IV. CONCLUSIONS

The primary aim of this paper was to develop the Webworld model by introducing an individual-based population dynamics. The Webworld model has been successful in constructing food webs with several realistic properties, based on simple population dynamics and foraging strategy optimisation. By developing a model whose basic assumptions correspond to a finer level of detail, the interactions between individuals rather than species-level descriptions, it becomes possible to explore the consequences of a range of behaviours enacted at the individual-level. For instance, at the level of the parent model it is possible to test robustness to different forms of the functional response, whose normal form is given by (3), but use of an individual-based model allows the more direct comparison of different forms of the reaction rate equations which are assumed to underlie species-level interactions. In addition, it has been shown that the stochastic model closely approximates the parent Webworld model when population sizes are large, but that when considering constructed food webs this is never an acceptable assumption, since there always exist some species which would not be viable for a significantly smaller ecosystem, and whose population demographics have a profound influence on the community as a whole.

A secondary aim in developing an individual-based version of the Webworld model was to establish a point on the way to an agent-based model. At the level of the individual, it becomes possible to model ecologically important processes such as predator-evasion, foraging choice through individual access to observations about prey distribution, and to include the effects of life-history decisions and mating strategy. Each of these can be expected to have effects on the population dynamics of the species and hence on the structure of the ecosystem, but it is not practically possible to create a simulation model which takes individuals with detailed behaviour as a starting point and from that constructs a food web structure. Instead we have adopted the strategy of taking a model known to produce realistic food webs, within which framework we can examine at various scales the influences that differences in the details of one level of abstraction have on the outcome of a broader picture. If a bridge can be built linking choice at the level of the individual at one end to ecosystem behaviour at the other, it will be possible to explore the consequences of the former on the latter despite the practical impossibility of computing the whole of an ecosystem at a sufficient level of detail to resolve detailed variation between individuals.

Some of the important results to come out of the preliminary work on the stochastic model performed in this paper relate to the effects of demographic stochasticity in different food web positions. In particular it has been shown that interactions between species significantly alter the magnitude of demographic fluctuations, and that taxonomic species forming part of a larger trophic species are more susceptible to these fluctuations than are species who share neither predators nor prey. The stochastic model broadly reproduces the results of the parent Webworld model in terms both of population dynamics and the construction of communities through immigration, although it is necessarily the case that extinction in the stochastic model occurs through fluctuations occasionally reducing a population to zero, rather than the mean population reaching a certain threshold as is the case in the parent model. Webs constructed in the parent model are robust to the imposition of the stochastic population dynamics, and a future line of enquiry would be to establish whether this is due to the degree to which the two sets of population dynamics are equivalent, or whether the method of constructing food webs through an evolutionary process of species addition selects for robustness to changes in relative species abundance, and hence provides stability against the demographic fluctuations.
